Overview Adaptation to new and changing conditions will be vital in the face of climate or other anthropogenic changes. Understanding and predicting a species' ability to adapt is thus key, and is especially relevant in crops needed to sustain food and fuel sources for the world's growing populations. Most ecologically or economically important phenotypic traits have a complex, quantitative genetic basis, yet we know relatively little about how quantitative trait evolution affects the genes underlying such phenotypes. **This research project aims to build models to understand and predict how phenotypic evolution affects, and is affected by, the underlying genetic architecture of quantitative traits.** Effect sizes of alleles and numbers of loci that contribute to a given phenotypic trait can vary in multiple ways. Selection on the overall phenotype and demographic processes may both affect the evolution of these underlying genetics and impact the genetic diversity available for adaptation. Taking advantage of the genotypic and phenotypic resources available for maize and its wild relative teosinte, I propose to: 1) build a simulation model that accurately recapitulates the number and effect size of genes underlying important phenotypic traits in teosinte; 2) use this model to predict the impact of demography and selection on traits in domesticated maize; 3) test predictions of the model in existing teosinte-maize mapping populations; and 4) apply the model to predict how genetic architecture impacts, and is impacted by, complex demography and local adaptation. This research will be conducted at the University of California, Davis, under the supervision of Dr. Jeffrey Ross-Ibarra and co-supervised by Dr. Kevin Thornton at the University of California, Irvine.

Intellectual Merit The proposed research will greatly expand our understanding of the adaptability of quantitative traits. Although most traits are quantitative, we know little about how the genes underlying such traits—their genetic architecture—limit or respond to evolutionary change. Does adaptation proceed mainly from new mutations or standing variation? Are adaptive traits primarily driven by few loci of large effect or many loci of small effect? Does population fluctuation change the architecture of quantitative traits? Statistical and sample size limitations have meant that traditional QTL and GWAS approaches have been unable to answer these questions. My simulation-based approach, calibrated using empirical data from maize and teosinte, has the potential to answer these and many other related questions about adaptation from and evolution of quantitative traits. Maize and teosinte serve as a perfect system for this study as the evolutionary history (domestication) is relatively well known and there is extensive genomic and phenotypic data for both ancestral (teosinte) and derived (maize) populations. Furthermore, this work will advance our understanding of plant biology and plant genomics and inform breeding efforts in maize and other species to adapting to future climate change.

Broader Impacts The impacts of this research will span both the scientific community and the broader public. The research will be made publicly available at all stages through online repositories of simulation and analysis code as well by public archiving the data. Additionally, I will make published results available on public pre-print servers, or when possible in open-access journals. I have a strong record of conference attendance that I will maintain in order to present results to the scientific community, and will also use my presence on Twitter and as a contributor to The Molecular Ecologist online blog to more frequently reach both scientific and public audiences. Furthermore, I will mentor undergraduate students in the lab, teaching skills on computational and genomics analyses and develop workshops on population and quantitative genetics and computational tools that I will organize to teach for graduate students at the Langebio research center in Irapuato, Mexico that is home to a number of collaborators to the Ross-Ibarra lab. I will also have the opportunity to develop undergraduate teaching modules for a 'flipped' version of the genetics class taught by Dr. Ross-Ibarra.

Project Description
A. Introduction

A critical goal of evolutionary biology today is to understand organisms' abilities to adapt to new or changing conditions. This is especially relevant in the face of global climate change and other increasingly common anthropogenic changes to the environment (Easterling, 2000). Most ecologically or economically important phenotypic traits have a complex, quantitative genetic basis, and considerable heterogeneity exists within and among species in their genetic architecture—the number of causal loci, their effect sizes, and allele frequencies (Orr, 2001; Slate, 2005). Yet we know very little about how the genetic architecture shapes, and is shaped by, the process of adaptation. In order to understand the maintenance of variation and adaptive potential of phenotypes of interest, we must understand how their genetic architecture changes as a result of evolutionary processes such as selection and demography, and how differences in genetic architecture may limit adaptive change. Such knowledge advances our understanding of the process of adaptation and can further benefit crucial goals such as improving crop yields under changing climates.

Nearly all knowledge of adaptation comes from population genetic theory focusing on individual loci or quantitative genetics theory that evaluates variances and ignores the underlying loci. Yet theoretical analysis of simple models of quantitative traits have shown that neither of these approaches can successfully predict the impact of evolutionary processes on the genetic diversity of loci underlying quantitative traits (Chevin and Hospital, 2008; Le Corre and Kremer, 2012). While quantitative trait locus (QTL) mapping approaches and genome-wide association studies (GWAS) have successfully identified a number of causative loci, these methods suffer from statistical issues limiting their utility for studying genetic architecture of adaptive traits (Spencer et al., 2009; Gibson, 2012; Thornton et al., 2013). Alleles missed in most QTL or GWAS studies may nonetheless be of central importance to adaption (Rockman, 2011; Mackay et al., 2009), and novel approaches are thus needed to understand how evolutionary processes affect the architecture of quantitative traits.

The genetic architecture of a trait is determined by a number of factors, including population size, mutation, demographic history, and the history of both purifying and positive selection. Population bottlenecks, for example, can lead to the loss of variation or maintenance of deleterious variation (e.g. Renaut and Rieseberg, 2015; Gunther and Schmid, 2010). Strong selection, such as that imposed during crop domestication, can fix large-effect loci (Brown et al., 2011). Both theoretical and empirical studies in humans have shown that the genetic architecture of human traits is shaped by the frequency and effect size of mutations (Thornton et al., 2013) as well as the interaction of demographic and selective histories (Fu et al., 2014; Gravel et al., 2011; Henn et al., 2015b).

This proposal aims to develop a simulation framework that allows explicit modeling of the evolution of the genetic architecture of a quantitative trait. This model will then be used to investigate how different factors shape the architecture of quantitative traits in maize and its wild relative teosinte. Thanks to its economic importance and history as a model genetic organism, extensive genomic (Wright et al., 2005; Hufford et al., 2012) and phenotypic (Wallace et al., 2014; Weber et al., 2009) data exist for both maize and teosinte, making it an ideal system in which to study processes affecting genetic architecture.

I propose four objectives which make use of the extensive knowledge and data available in the maize/teosinte system in order to develop an explicit genomic model of the evolution of a quantitative trait. Objective I. builds a simulation model fit to empirical estimates of the genetic architecture of phenotypically important traits in the wild ancestor of maize. Objective II. then uses simulations of maize domestication and comparisons to empirical data to understand how demography and selection combined affect the genetic architecture of phenotypes in maize. Objective III. empirically tests predictions made in Objectives I. and II. by comparing the effects of maize and teosinte alleles in a common genetic background in two mapping populations. Finally, Objective IV. uses our simulation model to predict changing genetic architecture in maize landraces as they spread across the Americas post-domestication and how variable their adaptability may be under

future selection regimes. This research has tremendous opportunity to further our understanding of the impact demography and selection have on phenotypic traits and their underlying genetics. Such knowledge greatly improves our ability to predict the effects of selection and changing environments on the genome as well as to exploit genetic diversity in crops for continued breeding or any species of concern for future conservation.

B. Research Objectives, Methods & Significance

I. Model the genetic architecture underlying phenotypes in teosinte

In Objective I. I will build a model to simulate the genetic architecture of phenotypes in the wild ancestor of maize, teosinte (*Zea mays* ssp. *parviglumis*). This model will then enable us to study the impacts of demography and selection on the genetic basis of phenotypic traits during domestication (Objective II.) and range expansion (Objective IV.).

In order to model the architecture of quantitative traits, I first need to understand the effects of mutation. The distribution of fitness effects (DFE) describes the consequences of mutations in terms of their impacts on an organism's fitness. Taking advantage of published (Chia et al., 2012) and ongoing whole-genome sequencing data in teosinte (see Data Management Plan), I will estimate the DFE in teosinte with the software DoFE (Keightley and Eyre-Walker, 2007; Stoletzki and Eyre-Walker, 2011). The resulting estimates of the fitness effects of new mutations can then be parameterized in terms of their effect on fitness-related quantitative traits (Keightley and Hill, 1988; Eyre-Walker, 2010), including yield, plant height, and flowering time.

This estimated DFE, combined with prior information on mutation (Clark et al., 2005) and recombination rates (Rodgers-Melnick et al., 2014), will then be used as input in simulation models of quantitative trait evolution in teosinte. Additional parameters necessary for our model (including dominance and the correlation between a trait and fitness) will be estimated using an Approximate Bayesian computation (ABC) approach (Beaumont et al., 2002). I will draw simulation parameters from a prior distribution and then compare summary statistics generated by simulation to observed data. By keeping the parameter draws that generate data most similar to the observed data, I can estimate the parameters' posterior distributions. I will take advantage of the library fwdpy (a Python implementation of fwdpp (Thornton, 2014), available at `https://github.com/molpopgen/fwdpy`) to write simulation code that explicitly models a quantitative trait evolving under a model of stabilizing selection. From each simulation, I will then perform genome-wide-association analysis in order to compare model results with observed data from published (Weber et al., 2009) and on-going (see Data Management Plan) analysis of 16 phenotypic traits in a natural population of teosinte. ABC will allow robust estimation of the necessary parameters from a set of several million such simulations.

Significance   Good estimates of the DFE are currently available for very few plants, and very few species in general. The DFE informs models of both population and quantitative genetics, including for example the genetic basis of heterosis (Mezmouk and Ross-Ibarra, 2014) or the genetic basis of complex diseases (Eyre-Walker and Keightley, 2007). Estimates of the DFE also contribute to future studies aiming to realistically simulate any distribution of mutation effects by further describing the variability of this distribution across species. Most importantly, this objective will produce a functioning model of selection on quantitative traits, allowing for the first time simulation of how evolutionary processes impact diversity at the genes underlying quantitative traits.

II. Model quantitative genetics of maize domestication

The model developed in Objective I. will enable simulation of quantitative traits under stabilizing selection. Here I will build upon this model to incorporate both demographic change and directional selection in order to investigate the impact of domestication on the genetic architecture of phenotypes of interest. Both demographic change associated with a domestication bottleneck and directional selection are expected to change the architecture of quantitative traits, but a detailed

Figure 1: Effect sizes from GWAS analyses in maize, grouped by trait category. Inset shows the largest effects. Ear traits, showing the largest effect sizes, were likely selected during maize domestication while the others were not. Figure from Brown et al. 2011.
understanding of how these two forces interact is lacking. I predict that traits under directional selection will be enriched for large effect alleles, as these contribute to greater phenotypic change, while traits under stabilizing selection are expected to have a deficit of large effect alleles since these are selected against to maintain the optimal phenotype (e.g. Figure 1).

To test this prediction, I will extend the simulation framework developed in Objective I. to include estimates of population size change during the domestication bottleneck and subsequent expansion (Wright et al., 2005). Using the parameters estimated for teosinte, I will simulate the same quantitative traits in a population undergoing a domestication bottleneck. This first analysis provides a null expectation of the genetic architecture of traits in the absence of directional selection. Differences between simulated and observed data (Wallace et al., 2014, and our own on-going analyses—see Data Management Plan) are informative for the history of selection on phenotypes. I will again use an ABC approach and GWAS of simulations performed using fwdpy to estimate the strength of selection on domestication phenotypes and re-simulate with more accurate selection parameters to assess how traits experiencing varying strengths of selection and with varying heritability have changed over the course of domestication.

Traits believed to evolve neutrally during domestication may only be impacted by demographic forces of the domestication bottleneck, while other traits are thought to have simultaneously experienced directional selection. Traits with high heritability or traits under stronger directional selection may change more dramatically than those evolving neutrally while subject to the bottleneck. I can thus test if allelic effect sizes have shifted their distribution mean or overall shape to more or fewer loci of large effect (Chevin and Hospital, 2008) depending on the strength of selection. Traits in maize such as kernel weight and kernel row number, among other ear-related traits (Figure 1), are expected to have been selected for crop improvement, while there are no strong reasons to suspect other traits such as total plant height were under selection. This suite of traits thus provides us with *a priori* predictions on which traits should show differences from our simple demographic simulations, and cases where these predictions are not matched may indicate genetic correlations with selected traits that could be confirmed by reanalysis of data from published GWA studies.

Significance The results of this Objective will allow us to distinguish the relative importance of demography and selection in determining the genetic architecture of maize. The impact of demography on the genetic architecture of traits is not well understood in any system. For example, how population bottlenecks affect deleterious variants of different effect size remains controversial in humans (Hancock et al., 2011; Henn et al., 2015a,b; Lohmueller, 2014; Simons et al., 2014). The effects of these processes vary depending on the degree of population size reduction and the length of time over which populations are bottlenecked (e.g. Caplins et al., 2014), but also have the potential to interact with selection. In crops, for example, it has been argued that smaller population sizes and selection together have lead to an increase in the frequency of deleterious alleles (Gunther and Schmid, 2010; Renaut and Rieseberg, 2015). Consistent with this, it has recently

been shown that genes associated with a number of quantitative traits in maize are enriched for deleterious alleles compared to randomly chosen genes (Mezmouk and Ross-Ibarra, 2014). Understanding this information is crucial for understanding variation in phenotype, designing breeding strategies, utilizing diversity from wild relatives, or even engineering new traits using biotechnology.

III. Validate model predictions in synthetic mapping populations

Models developed in Objective I. and II. lead to direct predictions of the genetic architecture of quantitative traits and how they should differ between maize and teosinte. To validate the predictions of these models, I will take advantage of two mapping populations containing mixtures of teosinte and maize alleles: a set of near isogenic lines of teosinte alleles introgressed into a maize background (Liu et al., In Press), and a synthetic population resulting from the cross of 11 teosinte and 26 maize parents (see Data Management Plan). Genotype and phenotype data are available for both populations, and if necessary I will add additional genotyping to augment marker density. I hypothesize that teosinte will have a wide range of effect sizes across loci, while in maize, domestication traits should have more large effect alleles than teosinte, and neutral traits more small effect loci due to purging of detrimental, large effect alleles during domestication.

I will perform a GWAS on these samples for the traits already used to calibrate our models. Identification of GWAS hits in regions of the genome coming from maize and teosinte will allow us to compare the effect size distribution of causal variants in a common environment and genetic background. With information on the correlation between phenotype and fitness, our model and simulations should be able to predict the difference in genetic architecture for new traits. I will thus perform a similar analysis for traits not included in our calibration to test the predictive ability of our model.

Significance   Objective I. and II. allow us to understand differences in genetic architecture based on fitting simulations to empirical data. This objective will demonstrate the predictive ability of our model for new phenotypes in a mapping population not used for model development; thus directly testing its potential utility in other systems.

IV. Investigate the impact of demography and local adaptation of maize landraces across the Americas

After domestication, maize spread across Central and South America, adapting to a variety of environments across a wide elevational range. These populations have experienced further demographic and selective pressures in addition to an initial domestication bottleneck. For example, South American populations are inferred to have experienced a second severe bottleneck (Takuno et al., 2015), and more generally populations expanding geographically are likely to have experienced serial founder effects that can change allele frequencies in unexpected ways due to allele surfing (Klopfstein et al., 2005). The effect of range expansion on deleterious alleles remains controversial (Henn et al., 2015a,b; Simons et al., 2014; Sudmant et al., 2015), and even less is known about its impact on quantitative traits. Changing selection pressures from both new environments and artificial selection by different human populations likely also interact with these demographies.

In this objective, I will simulate quantitative traits for populations undergoing multiple shifts in selection as well as additional demographic change to incorporate range expansion and further bottlenecks. I hypothesize that these combined forces will lead to stronger divergence among populations at alleles with large phenotypic effects, and that these differences will increase with both geographic and environmental distance from maize's origin of domestication in SW Mexico. I will compare these predictions to GWAS results from publicly available genotype, phenotype, and environmental data from nearly 5,000 landraces from across the Americas (Hearne et al., 2015). Furthermore, I predict that these changes in genetic architecture may limit future adaptability of populations. To test this, I will impose identical shifts in selection on the resulting genetic architectures across traits and populations to assess the response to selection in terms of magnitude and

speed of phenotypic change. I hypothesize that architectures best able to respond to selection are those with large effect alleles already suited to the new selective pressure, but that novel selection pressures over shorter time scales may require more loci of small effect to sufficiently adapt.

Significance   This Objective allows assessment of how complex demography and changing selection regimes affect the genetic architecture of local adaptation to different conditions. It will also further test predictions on how future adaptation may be impacted by current genetic architecture (Yeaman, 2015). Understanding the characteristics that lead to this improved ability to adapt allows for more predictability of evolutionary processes and better methods of artificial selection or conservation efforts to ensure the persistence of crops and other species of importance for biodiversity into the future.

C. Training Objectives

This fellowship will provide me with an ideal opportunity to learn the skills needed to enhance my ability to conduct cutting edge research in the fields of genomics and computational biology, both areas in which I expect to continue my future research and which are greatly expanding in evolutionary biology. I will gain many skills related to genomic data analysis through these projects, learning bioinformatics and analysis skills for large datasets. I have limited experience working with genomic data from my dissertation, thus making this a vital step in my career. Genomic technology and data are growing at an incredibly fast pace, and working directly with such data will teach me the most up to date, accurate, and efficient approaches. I will also improve my computational biology skills through the proposed simulations, learning a new and useful programming language, Python, that I can apply throughout this research and my future research in evolutionary biology.

D. Career Development & Future Research

My career goal is to develop an innovative research program in evolutionary biology, studying population genetics and processes that impact genetic diversity. I believe such research is key for the future, not only for the field of evolutionary biology, but also in applied scenarios such as understanding prevalence of genetic diseases in humans, adaptation of species to climate change, or strategies to improve agricultural products for a growing world population. My dissertation research has approached some of these questions in a more theoretical and less applied mindset. The work I will conduct during this fellowship would have more direct potential for application in the field of maize agriculture. This is necessary and vital experience for my career development as I decide between pursuing a more applied research program, potentially in industry or government research scientist positions, or in pursing a career as an academic researcher at a university.

The skills I will develop during this fellowship, as described in section C, will benefit my career and put me on the cutting edge for analyses of the newest genomic data and the most recent computational approaches for biological simulations. Interacting with Dr. Ross-Ibarra, as well as other researchers at UC Davis, and with Dr. Kevin Thornton at UC Irvine, will be both intellectually stimulating and rewarding experiences that will help me accomplish my career goals. Drs. Ross-Ibarra and Thornton are both at the forefront of a popular movement for open science, making all stages of the research process transparent to any interested parties, and providing products such as data and code immediately and publicly. This is a work ethic I strongly agree with and hope to contribute to as an independent researcher. Our work together will better equip me with the tools and experience that make open science efficient, and rewarding for all. I believe that this will prepare me to be a competitive, knowledgeable, and independent researcher able to conduct interesting and useful research throughout my future research program on topics of local adaptation, demographic history, population structure and genetic architecture of important traits. Furthermore, Dr. Ross-Ibarra has an excellent track record of helping his post-doctoral fellows secure promising positions for their future careers, including three assistant professorships at universities, three research scientist positions in the seed industry, one at an NGO, and one in the USDA.

E. Sponsoring Scientists and Host Institution

The University of California Davis (UCD) is the ideal place to conduct the proposed research. UCD has a world-renowned program in evolutionary biology and faculty in population genetics who are leaders in the field. Jeff Ross-Ibarra is an expert on teosinte, maize, its domestication, and the associated population genetics and genomics of the system. Kevin Thornton is an accomplished quantitative geneticist and computational biologist at UC Irvine, who will contribute greatly to this research. Both will serve as effective and capable mentors for my post-doctoral research. In particular, Jeff has been studying the maize/teosinte system for years with a great network of collaborators providing vast resources of data. His work has contributed largely to our knowledge of this system, and more generally on domestication and adaptation as evolutionary processes. Kevin is the developer and maintainer of fwdpy, the python package proposed for completing the simulations. He will thus serve as a great resource in terms of knowing the exact capabilities of the simulation method and assumptions of its model that must be taken into account. Furthermore, the Department of Ecology and Evolution, the Department of Plant Biology, and the Department of Plant Sciences at UCD have many exceptional faculty doing research relevant to my interests, providing many research groups to interact with on a daily basis for potential collaborations or feedback on this research. I look forward to interacting with scientists interested in population genetics, such as Graham Coop, and in adaptation, such as Johanna Schmitt. UCD and UC Irvine both have extensive computing resources for our proposed work with access to dedicated processors and nodes across multiple clusters of large RAM capabilities (see Sponsoring Scientist Statement), and as described, vast sources of knowledge and experience on the topics I plan to investigate, ensuring the success of this work. I am excited to join and contribute to such an active and vibrant scientific community.

F. Milestones & Timeline

Year 1: Estimate DFE in teosinte; design model & perform ABC (Obj. I)
        Manuscript on genetic architecture of important phenotypic traits in teosinte
Year 2: Model domestication & selection, validate with empirical data (Obj. II, III)
        Manuscript on evolution of genetic architecture during domestication of maize
Year 3: Model local adaptation, population expansion (Objective IV)
        Manuscript on impact of demography and selection across maize landraces

G. Broader Impacts

The proposed research will have wide-ranging impacts for both the public and the scientific community. I will ensure that my results are publicly available at all stages of these projects by maintaining code and scripts online at my GitHub account. This will allow other researchers to access analysis methods or data cleaning tools as well as simulation details and parameters which can provide a building block from which further research can be conducted. I will present new findings at international conferences and submit publications to open-access pre-print servers. I will also be able to broadcast my work more widely to the public through a strong online presence I maintain on Twitter and The Molecular Ecologist, a blog I have contributed to in the past. I will also contact local schools where I can tailor seminars to students of different age ranges and topics of interest. These will range in topic from more general science on the origins of crops and domestic species to more in-depth presentations of my research and evolutionary biology as a field that are appropriate for high school students interested in pursuing further study in biology or the sciences more broadly. The impacts of this research on corn as a useful crop species for both food and fuel resources is also of an innate broad impact, as understanding the genetics underlying adaptation will ensure a viable future for such crop species in the future. Lastly, this research will contribute greatly to my own career development, improving my knowledge on genomics and working in an economically important crop species. I will be able to learn these vital tools as well as to teach them to undergraduate students in the lab and into the future as the field of genomics continues to grow.

D. Grants and Awards

Cordula and Gunter Paetzold Fellowship *UBC* $18,000CAD   2015 – 2016

Declined; Zoology Graduate Fellowship *UBC* $11,000CAD   2015 – 2016
Ann and William Messenger Graduate Fellowship *UBC* $700CAD   2015
Zoology Graduate Fellowship *UBC* $11,000CAD   2014 – 2015
Frieda Granot Graduate Scholarship in Interdisciplinary Research *UBC* $200CAD   2013 – 2014
Theodore E Arnold Fellowship *UBC* $7,750CAD   2013 – 2014
Patrick David Campbell Graduate Fellowship *UBC* $8,050CAD   2013 – 2014
Declined; Zoology Graduate Fellowship *UBC* $10,000CAD   2013 – 2014
BRITE Fellowship *UBC* $10,500CAD *per annum*   2011 – 2013

E. Synergistic Activities

1. **Working Groups:** Participated in the NESCent Reproducible Science Hackathon (2014), a 21-member working group aimed at developing a curriculum and workflow for teaching reproducible science to researchers of any background. Participated in the SimBank NESCent Catalysis Meeting (2014) which was a 25-member working group to create a collection of openly available simulation results to facilitate testing of statistical population genetic and phylogeographic methods.

2. **Teaching:** Teaching assistant for Fundamentals of Evolutionary Biology (Fall 2012-Spring 2013) where I taught three sections per term of 45 students each and lead discussion-based tutorials. Teaching assistant for Fundamentals of Biostatistics (Fall 2013, 2014, 2015). Taught two sections of 70 students total in 2013, and in 2014 and 2015 served as the lab coordinator for 254 and 276 students enrolled in the course, respectively, while teaching one section of 36 and 35 students respectively.

3. **Service:** Served as a Graduate Student Council Member for the American Society of Naturalists (2013-2016, chair 2015-2016). Served as the graduate student representative on the 2014 evolutionary biology CRC2 job search for the Department of Zoology, University of British Columbia. Organize the Biodiversity Research Centre's weekly evolution discussion group (2014-2016), for students, post-docs, and faculty from the departments of Zoology, Botany, Forestry, and Fisheries to discuss current papers in evolutionary biology. Reviewer for *Molecular Ecology Resources, New Phytologist, Ecology and Evolution, Tree Genetics & Genomes*.

4. **Outreach:** Volunteer mist-netting and bird banding with local Vancouver non-profit organization Wild Research (2013-2015) where I participated in winter, spring migration, and fall migration bird monitoring at Iona Island Bird Observatory, taught volunteers proper bird handling, aging, data collection, and mist net extraction techniques, and assisted in educating public visitors to the station about the species conservation and monitoring, and the general tasks of running a banding station.

Data Management Plan

Data Types

This proposal will make use of existing maize and teosinte datasets from multiple sources as well as data currently being generated. Unless additional genotyping is needed in Objective III., this project will only generate simulated datasets. These real-world maize and teosinte datasets are used within all objectives of the proposal, while simulated data is produced within Objectives I.,II., and IV..

Sequence, Genotype, and Phenotype Data   This project will make use of both published data as well as data generated or currently being generated as part of a related Plant Genome project (Biology of Rare Alleles IOS-1238014) of which sponsoring scientist Dr. Ross-Ibarra is a Co-PI. As part of this project, Dr. Ross-Ibarra's group is currently in the process of sequencing 70 teosinte and 55 maize genomes to high depth. These sequences should be complete by the end of 2015 and will be made publicly available early 2016 via the group website (`www.panzea.org`). The individuals used for genome sequencing are also the parents of two large mapping populations of ∼5000 progeny. Both populations have been genotyped and phenotyped for a number of traits including seed yield, flowering times, and plant height, and would be used for comparisons in Objectives I. and II.. Finally, the same project has developed, genotyped, and phenotyped a synthetic population of 11 teosinte and 26 maize parents, resulting in a population that is roughly 12% teosinte genes, 40% B73 (the reference genome line), and 2% from 25 other inbred maize lines. This latter population will be used in Objective III. to compare model predictions to maize and teosinte regions segregating in a common population. All of these data are currently available from collaborators. Publication of results from analyses of these data must await publication of collaborators' GWAS analyses, but as these are currently underway, and comparisons with empirical data would likely not begin until early 2017 at the soonest, we do not foresee this being an issue. In the unlikely event of a problem in the generation of that data, existing data is also available publicly for teosinte (Weber et al., 2009) and maize (Wallace et al., 2014) as well as ∼1500 maize genomes through the HapMap 3 project (Bukowski et al., 2015) and 4,000 landraces each with 1 million SNPs and several phenotypes (Hearne et al., 2015).

Simulated Data   Outputs from simulations will consist of genotype data and allele effect sizes from genomic regions representing important phenotypic traits. This data will be organized to describe how users can interpret the data in terms of what phenotype each region represents and what file corresponds to each demographic and selective scenario simulated. All of this information will be contained in Readme files associated with each directory of simulated datasets. Additionally, links to the exact code used (hosted on GitHub) and random number seeds will be included in publications, so that the exact simulated data can be replicated in the future if necessary.

General Organization

All obtained and generated datasets will be stored locally and remotely backed up on the 300 terabyte array for the Ayala School of Biological Sciences. In the rare event of simultaneous failure of these storage facilities, maize and teosinte datasets can be re-obtained from original and simulated datasets can be re-generated from the same random seed to produce identical results. In addition to data, analysis and simulation scripts will be stored locally and remotely on my GitHub account. I will use GitHub to version control all scripts so that previous versions are not deleted nor is confusion of the proper published version a problem. Using version control and GitHub are already protocols I follow currently and will provide no future difficulty in maintaining this workflow.

Readme files can be generated for each set of analysis or simulation scripts that serve as a sort of metadata for reproducing the analyses within and instructions for future users to understand how each script is run.

Data Archiving, Plan for Sharing, Public Access Policy

The existing maize and teosinte datasets are all either currently publicly available or will be made publicly available during the completion of this research.

Simulated data will be publicly archived concurrently with publication of the research results. These datasets will be archived on Dryad Digital Repository, unless otherwise directed to another appropriate, publicly accessible data archive by the publication journal. Detailed metadata will be provided to ensure reproducibility of the studies. The scripts used to generate these data files and conduct analyses will be made available with detailed instructions on my GitHub account. I will post links to all data sources on my academic website, which is a standard I already maintain.

Since all data is either simulated or comes from plant datasets, there will be no privacy concerns for sharing data.

Dissertation Summary - Kimberly J. Gilbert

A major obstacle in evolutionary biology is the difficulty of population genetic inference in the face of confounding factors, such as demographic history. My dissertation work has focused on several topics related to this broad area of research:

1. Evaluating the ability of statistical genetic methods to estimate effective population sizes in the face of migration (Gilbert and Whitlock, 2015)
2. Assessing the factors affecting local adaptation at range edges during species expansion
3. Validating SNP loci under selection for adaptation to climate in lodgepole pine (*Pinus contorta*)

Effective population size, N_e, is a fundamental parameter in population genetics, evolutionary biology, and conservation biology, yet its estimation can be fraught with difficulties. Several methods to estimate Ne from genetic data have been developed that take advantage of various approaches for inferring N_e. The ability of these methods to accurately estimate N_e, however, has not been comprehensively examined. This part of my dissertation work employed seven of the most cited methods for estimating N_e from genetic data (Colony2, CoNe, Estim, MLNe, ONeSAMP, TMVP, and NeEstimator including LDNe) across simulated datasets with populations experiencing migration or no migration. The simulated population demographies were an isolated population with no immigration, an island model metapopulation with a sink population receiving immigrants, and an isolation by distance stepping stone model of populations. We found considerable variance in performance of these methods, both within and across demographic scenarios, with some methods performing very poorly. The most accurate estimates of N_e can be obtained by using LDNe, MLNe, or TMVP; however each of these approaches is outperformed by another in a differing demographic scenario. Knowledge of the approximate demography of population as well as the availability of temporal data largely improves N_e estimates.

Species range edges have boundaries that cannot always be explained ecologically or geographically, which leaves the question of what evolutionary forces may prevent populations at range edges from adapting and expanding the species range further. A large body of theoretical work has investigated many evolutionary parameters' effects on local adaptation in edge populations, but one area lacking in research is the effect of landscape heterogeneity with the ability to locally adapt. This study investigates how realistic, heterogeneous, and patchy environmental gradients (compared to linear gradients that previous studies investigate) may interact with dispersal distance and the availability of mutational input. I found a relationship between steepness of landscape and availability of mutations on the ability to colonize new landscape. Furthermore, as environmental heterogeneity increases, migration load (reduction in fitness due to dispersal away from an area previously adapted to) increases, and local adaptation becomes more difficult, especially in smaller populations at the range edge, slowing the speed of expansion across the landscape.

History of range expansions can confound many inferences that population genetics aims to understand. Identifying loci that underlie traits contributing to local adaptation is one such inference that is a major goal in evolutionary biology today. Lodgepole pine (*Pinus contorta*), a major timber tree in the Pacific Northwest, has a history of expansion post-glaciation, and either one or putatively a second glacial refugia from which this expansion occurred. Climate change is spurring foresters to plant trees for future harvest that will be best adapted to future climates for optimal yield, hence identifying loci underlying adaptation to climate change is a key goal to identify the best-suited trees. I am conducting a validation study of SNP loci previously identified through GWAS, genotype-environment association, and F_{ST} outlier tests to assess how often these methods may produce false positives as a result spatial autocorrelation of neutral alleles with gradients in environmental variables (i.e. temperature and precipitation) due to non-adaptive processes. I have sampled a provenance trial (common garden study) in British Columbia to compare performance and conduct environment-allele correlations across populations from a range of native temperatures planted at test sites of varying temperature from which I will be able to test if predicted alleles do indeed show increased performance in mature, natural-grown trees.

Sponsoring Scientist Statement

I. Brief description of the research projects in the host research group(s), including a statement of current and pending research support

Research in the Ross-Ibarra lab focuses on the evolutionary genetics of maize and teosinte, including studies of local adaptation, genome evolution, and experimental evolution. The Thornton lab focuses on fundamental questions relating evolutionary processes to the interpretation of population- and quantitative- genetic data.

The proposed project build on current projects in both labs. Working with theory and software built by the Thornton lab as part of a current NIH R01, Kim will seek to develop a model of the evolution of quantitative traits undergoing both demography and selection. Kevin's proposal aims to build software and apply it to evolutionary questions in *Drosophila*; Kim's use of these models and application to maize thus complements these efforts. Kim will apply these models to the maize and teosinte system used in the Ross-Ibarra lab, including comparisons to data currently being generated from Ross-Ibarra's currently funded NSF proposal. This grant seeks to investigate the biology of rare alleles and take advantage of functional annotation to predict phenotypes; Kim's modeling will complement this work by seeking to clarify the evolutionary processes that lead to observed differences among taxa. Rather than lead to improved phenotypic prediction, Kim's proposal improves our ability to predict how the genetic basis of phenotypes changes.

Current Support

Title: Adaptive gene flow from teosinte to highland maize in central Mexico **Agency:** UC MEXUS (Ross-Ibarra, Co-PI) **Amount:** $24,897 **Dates:** 07/15 – 12/16 **Calendar Person-months:** 0.24
Title: Functional genomics of maize centromeres **Agency:** NSF-PGRP (Ross-Ibarra, Co-PI) **Amount:** $754,409 **Dates:** 06/10 – 5/16 **Calendar Person-months:** 2.4
Title: US Mexico planning visit and workshop to assess the genomic basis of local adaptation in maize **Agency:** NSF-CNIC (Ross-Ibarra, Co-PI) **Amount:** $36,450 **Dates:** 09/14 – 12/16 **Calendar Person-months:** 0.5
Title: Biology of rare alleles in maize and its wild relatives **Agency:** NSF-PGRP (Ross-Ibarra, Co-PI) **Amount:** $3,221,212 **Dates:** 05/15 – 4/18 **Calendar Person-months:** 2
Title: Population genomics of polygenic adaptation. **Agency:** NIH/NIGMS **Amount:** $1,000,000 (Thornton, PI) **Dates:** 09/2015 – 08/2019 **Calendar Person-months:** 3

Pending Support

Title: Evolutionary genomics of maize **Agency:** HHMI (Ross-Ibarra, PI) **Amount:** NA (decided by agency) **Dates:** 07/16 – 6/21 **Calendar Person-months:** 1
Title: Research PGR: The genetics of highland adaptation in maize **Agency:** NSF PGRP (Ross-Ibarra, PI) **Amount:** $4,531,773 **Dates:** 05/16 – 4/21 **Calendar Person-months:** 2.4
Title: Research PGR: The evolutionary role of hybridization and introgression in the genus Zea **Agency:** NSF-DEB (Ross-Ibarra, Co-PI) **Amount:** $415,775 **Dates:** 07/16 – 6/19 **Calendar Person-months:** 0.6

II. Description of how the research and training plan for the applicant would fit into and complement ongoing research of the sponsor(s) as well as an indication of the personnel with whom the Fellow would work.

The proposed research nicely extends current work in the Ross-Ibarra lab on the impacts of demography and selection on allele frequencies to their effects on complex phenotypes. By investigating how genetic architecture may change, this proposal also shows potential to be extremely informative of work underway on complementation and the basis of hybrid vigor. Additionally, the work will complement existing research in the Thornton lab on polygenic adaptation. The Thornton lab is primarily concerned with the analysis of human and *Drosophila* data sets. The proposed research will add an important perspective from a major model plant system.

Kim will be encouraged to interact with other postdoctoral fellows and graduate students in both labs. These interactions provide opportunities to work outside the focus of the current proposal, to develop new collaborations, and to coauthor additional publications. We hope and expect that some of these interactions may evolve into formal collaborations on projects not involving either sponsor.

III. Explanation of how the sponsor(s) will determine what mentoring the applicant needs in research, teaching, and career development skills and how these would be translated into a specific plan that fosters the development of the applicant's future independent research career.

Research We have planned a rigorous guided reading discussion to ensure Kim gets quickly up to speed on the necessary quantitative genetics theory as well as the relevant literature on quantitative traits in maize, and have discussed with Kim online and formal coursework options for learning python programming. We will both meet with Kim weekly to ensure progress on the research; Jeff also has an open-door policy encouraging interaction with lab members outside of formal meeting times.

Writing We work with lab members to develop an initial outline of their papers, but lab members are expected to prepare a complete first draft of manuscripts and figures. This responsibility is reflected in the fact that postdocs and students are not only first but also co-corresponding author on their papers. We then work with lab members to revise and edit their manuscript in a process that often goes through numerous rounds of revision. Manuscripts are shared with other lab members and colleagues to encourage practice providing (and receiving) constructive criticism, and final versions of our papers are posted as preprints online upon submission to take advantage of community feedback that can be incorporated into the published paper. One clear goal will be first authorship on submitted papers, with the expectation of approximately one first author paper per year of duration of the postdoc. We will also encourage lab members to participate in other writing activities, including blog posts on our journal club papers, formal reviews for journals, and grant proposals. The Ross-Ibarra lab has a documented history of successful funding with postdoctoral scholars as Co-PIs, and these efforts provide valuable training (and even initial funding) for the scholars' future academic careers.

Teaching Postdoctoral fellows in the Ross-Ibarra Lab are encouraged to participate in formal teaching opportunities including development of lectures for a graduate course on ecological genomics or a large undergraduate genetics lecture course. Jeff works with the postdoctoral fellow to develop the lecture and provides feedback on teaching style and and content afterwards. Kim will also be encouraged to practice presenting her work to broad audiences both in joint lab meetings and formal seminars at UC Davis and UC Irvine, as well as at local (e.g. Bay Area Population Genomics) and international (SMBE, PAG) meetings. Both Jeff and Kevin provide guidance and feedback on such presentations.

Mentoring Another important aspect of training will be experience mentoring graduate students and undergraduates. Previous efforts to encourage such supervision in our labs have been very successful, with postdoc-mentored students presenting conference posters on their research or earning authorship on papers. Supervisory experience has proven helpful for postdocs applying for jobs, especially in industry.

Career Development During weekly meetings we will focus not only on current progress on the project but also on progress towards Kim's broader career goals. We will encourage Kim to take advantage of formal infrastructure for professional development in place at UC Davis, including training in responsible conduct of research, grantsmanship, mentoring, career development, authorship of journal papers, and teaching. We will encourage attendance at conferences to present results and build relationships with other leaders in the field. The Ross-Ibarra lab has a proven record of success in placing postdoctoral scholars in careers industry, government, nongovernmental research organizations, and academic positions, and we will continue to encourage postdocs to explore a range of career opportunities.

IV. Description of the role the sponsors will play in the proposed research and training and the other resources that will be available to the Fellow to complete his or her training plan during the fellowship.

Kevin will primarily help Kim to develop the necessary models and code, and Jeff will primarily help in analysis of simulation and empirical data and guidance in the interpretation of the results. However, Kim will meet weekly with both advisors to facilitate research interactions among the sponsors and ensure that everyone is in agreement on progress and continued plans. We will additionally formally address long terms goals and progress in separate meetings every 6 months. Though Kim will be based primarily in the Ross-Ibarra lab at UC Davis, we expect the development of the simulation framework will involve extended visits to the Thornton lab at UC Irvine.

UC Davis is regularly ranked as one of the top three centers of research in both plant and evolutionary biology. Kim will have access to a broad set of discussion groups and seminars, as well as to the experience and guidance of world-class set of scientists that can help her with all aspects of the development of her research, engagement in diversity issues, and career path.

Both labs have access to extensive computational resources. The Ross-Ibarra lab is a contributing partner in the college computer cluster, giving the lab dedicated access to 192 processors, with the opportunity for use of nearly 800 additional CPU as resources allow. Recent additions to the cluster have provided it with additional CPU as well as six new shared high-memory (512Gb RAM) nodes, one of which is dedicated to the Ross-Ibarra lab. Dr. Ross-Ibarra is a faculty member of the UC Davis Genome Center, a large facility that includes bioinformatics and genotyping cores as well as access to additional computational facilities. At UCI, the Thornton lab has 192 processors divided amongst 3 64-core machines. Campus-wide, the lab has access to an additional $\sim$3,000 processors in a mix of high- and low- priority queues. With respect to this project, we have effectively unlimited storage in the form of a 300 terabyte array for the Ayala School of Biological Sciences.

V. Description of the limitations, if any, be placed on the Fellow regarding the research following the fellowship.

Kim would be free to continue and expand on the proposed work either in maize or other systems and to continue development of fwdpy simulation code.
